ABSTRACT

We present a technique to identify the most probable dynamical formation scenario for an observed binary or triple system containing one or more merger products or, alternatively, to rule out the possibility of a dynamical origin. Our method relies on an analytic prescription for energy conservation during stellar encounters. With this, observations of the multiple star system containing the merger product(s) can be used to work backwards in order to constrain the initial orbital energies of any single, binary or triple systems that went into the encounter. The initial semi-major axes of the orbits provide an estimate for the collisional cross section and therefore the time-scale for the encounter to occur in its host cluster.

We have applied our analytic prescription to observed binary and triple systems containing blue stragglers, in particular the triple system S1082 in M67 and the period distribution of the blue straggler binaries in NGC 188. We have shown that both S1082 and most of the blue straggler binaries in NGC 188 could have a dynamical origin, and that encounters involving triples could be a significant contributor to BS populations in old open clusters. In general, our results suggest that encounters involving triples could make up a significant fraction of those dynamical interactions that result in stellar mergers, in particular encounters that produce multiple star systems containing one or more blue stragglers.

Key words: stars: blue stragglers – galaxies: star clusters – stellar dynamics.

1 INTRODUCTION

It has been known for some time that encounters, and even direct collisions, can occur frequently between stars in dense stellar systems (Hills & Day 1976; Hut & Verbunt 1983; Leonard 1989, e.g.). In the cores of globular clusters (GCs), the time between collisions involving two single stars can be much shorter than the cluster lifetime (Leonard 1989). The time between encounters involving binary stars can be considerably shorter still given their much larger cross sections for collision. In globular and, especially, open clusters (OCs) with high binary fractions, mergers are thought to occur frequently during resonant interactions involving binaries (e.g. Leonard & Linnell 1992). What's more, collision products have a significant probability of undergoing more than one collision during a given single-binary or binary-binary interaction since the initial impact is expected to result in shock heating followed by adiabatic expansion, in-

creasing the cross section for a second collision to occur (e.g. Fregeau et al. 2004).

Several types of stars whose origins remain a mystery are speculated to be the products of stellar mergers. Blue stragglers (BSs) in particular are thought to be produced via the addition of fresh hydrogen to the cores of low-mass main-sequence (MS) stars. Recent evidence has shown that, whatever the dominant BS formation mechanism(s) operating in both globular and open clusters, it is likely to in some way depend on binary stars (Knigge, Leigh & Sills 2009; Mathieu & Geller 2009). The currently favored mechanisms include collisions during single-binary and binary-binary encounters (e.g. Leonard 1989), mass transfer between the components of a binary system (e.g. Chen & Han 2008a,b) and the coalescence of two stars in a close binary due to perturbations from an orbiting triple companion (e.g. Eggleton 2006; Perets & Fabrycky 2009).

A handful of spectroscopic studies have revealed that in some GCs there exist BSs with masses exceeding twice that of the MS turn-off (e.g. Shara, Saffer & Livio 1997; Knigge et al. 2008). Such massive BSs must have been

* E-mail: leighn@mcmaster.ca (NL); asills@mcmaster.ca (AS)

formed from the mergers of two or more low-mass MS stars since they are too massive to have been formed from mass transfer. In a few cases, this can also be argued for entire BS populations using photometry. For instance, Chen & Han (2008b) performed detailed binary evolution calculations to study dynamical stability during mass transfer from an evolving giant star onto a MS companion. Based on their results, it can arguably be inferred that most BSs in NGC 188 are sufficiently bright that they probably could not have formed from mass transfer alone. If true, this suggests that most of these BSs must be the products of stellar mergers. Regardless of the dominant BS formation mechanism(s) operating in dense star clusters, dynamical interactions should play at least some role. For example, even if blue stragglers are formed as a result of binary evolution processes such as mass transfer, the progenitor binaries themselves should have been affected by at least one dynamical interaction over the course of their lifetime.

Numerous scattering experiments have been performed to explore the outcomes of binary-binary and, in particular, single-binary encounters (e.g. McMillan 1986; Sigurdsson & Phinney 1993; Fregeau et al. 2004). Most of the earliest of these studies were performed in the point-particle limit, ignoring altogether the often non-negligible implications of the stars' finite sizes (e.g. Hut & Bahcall 1983; Mikkola 1983). Later, more realistic simulations clearly demonstrated the importance of taking into account the dissipative effects of tidal interactions and direct contact between stars (e.g. McMillan et al. 1987; Cleary & Monaghan 1990). As a result of the increased number of free parameters for the encounters and the longer integration times required to run the simulations to completion, few studies have been conducted to explore the outcomes of binary-binary encounters or interactions involving triple systems.

In this paper, we introduce an analytic technique to constrain the most probable dynamical origin of an observed binary or triple system containing one or more merger products. Provided the observed system is found within a moderately dense cluster environment with binary and/or triple fractions of at least a few percent, the probability is often high that it formed from a merger during an encounter involving one or more binary or triple stars. In Section 2, we present an equation for energy conservation during individual stellar encounters and outline the process for applying our technique. Specifically, we present a step-by-step methodology to evaluate whether or not an assumed dynamical history could have realistically produced an observed system and describe how to determine the most probable dynamical formation scenario. In Section 3, we apply our technique to a few observed binary and triple systems thought to contain merger products, in particular a triple system that is thought to contain two BSs and the peculiar period-eccentricity distribution of the BS binary population in NGC 188. We discuss the implications of our results in Section 4.

2 METHOD

In this section, we present a general prescription for conservation of energy during stellar encounters. We will limit the discussion to typical interactions thought to occur in glob-

ular and old open clusters, although our technique can be generalized to any choice of parameter space. The types of encounters of interest in this paper will predominantly involve low-mass MS stars with relative velocities at infinity ranging from $\lesssim 1$ km/s to ~ 10 km/s (e.g. Leonard 1989; Sigurdsson & Phinney 1993). Our technique describes how to isolate the most probable dynamical formation history for an observed binary or triple containing one or more merger products by providing an estimate for the time required for a given interaction to occur in a realistic cluster environment.

We begin by assuming that an observed system was formed directly from a dynamical interaction (or sequence of interactions). In this case, the observed parameters of the system provide the final distribution of energies for the system resulting from the interaction(s). After choosing an appropriate dynamical scenario (i.e. whether the objects involved in the interaction(s) are single, binary or triple stars), we can work backwards using energy conservation to constrain the initial energies going into the encounter. This provides an estimate for the initial orbital energies and therefore semi-major axes of any binaries or triples going into the interaction. This in turn gives the cross section for collision and hence the time required for the hypothesized interaction(s) to occur.

Since the formation event must have happened in the last τ_{BS} years, where τ_{BS} is the lifetime of the merger product, a formation scenario is likely only if the derived encounter time-scale is shorter than the lifetime of the merger product(s). Conversely, if the derived encounter time-scale is longer than the lifetime of the merger product(s), then that dynamical formation scenario is unlikely to have occurred in the last τ_{BS} years. In general, the shorter the derived encounter time-scale, the more likely it is that one or more such encounters actually took place within the lifetime of the merger product(s). Finally, if the derived encounter time-scale is longer than τ_{BS} for every possible dynamical formation scenario, then a dynamical origin is altogether unlikely for an observed multiple star system containing one or more BSs. Either that, or the encounter time-scales must have been shorter in the recent past (or, equivalently, the central cluster density must have been higher).

2.1 Conservation of Energy

Consider an encounter in which at least one of the two bodies involved is a binary or triple star. Though a complex exchange of energies occurs, energy must ultimately be conserved in any dynamical interaction. The total energy that goes into the encounter must therefore be equal to the total

energy contained in the remaining configuration:

$$\begin{aligned}
 & \sum_i^{N_i} \Omega_i(I_i, \omega_i) + \sum_i^{N_i} W_i(m_i, X_i, Z_i, \tau_i) \\
 & \sum_i^{N_i} U_i(m_i, X_i, Z_i, \tau_i) + \sum_j^{S_i} T_j(M_{cl}, M_j) + \\
 & \sum_k^{M_i} \epsilon_k(\mu_k, M_k, a_k) = \sum_{ii}^{N_f} \Omega_{ii}(I_{ii}, \omega_{ii}) + \\
 & \sum_{ii}^{N_f} W_{ii}(m_{ii}, X_{ii}, Z_{ii}, \tau_{ii}) + \sum_{ii}^{N_f} U_{ii}(m_{ii}, X_{ii}, Z_{ii}, \tau_{ii}) \\
 & + \sum_{jj}^{S_f} T_{jj}(M_{jj}) + \sum_{kk}^{M_f} \epsilon_{kk}(\mu_{kk}, M_{kk}, a_{kk}) + \Delta,
 \end{aligned} \tag{1}$$

where N_i , S_i and M_i are the total number of stars, objects (single, binary, triple or even quadruple stars) and orbits, respectively, that went into the encounter. Similarly, N_f , S_f and M_f are the total number of stars, objects and orbits remaining after the encounter.

We let $\Omega_i = \Omega_i(I_i, \omega_i)$ represent the bulk rotational kinetic energy in star i , which is a function of the star's moment of inertia I_i and angular rotation rate ω_i :

$$\Omega_i(I_i, \omega_i) = \frac{1}{2} I_i \omega_i^2 \tag{2}$$

The moment of inertia is in turn a function of the density profile within a star, which changes along with its internal structure and composition as the star evolves. The moment of inertia is given by (Claret & Gimenez 1989):

$$\begin{aligned}
 I &= \frac{8\pi}{3} \int_0^R \rho(r) r^4 dr \\
 &= \beta^2 m R^2,
 \end{aligned} \tag{3}$$

where β is the radius of gyration. For example, a typical $1 M_\odot$ star in an old open cluster having an age of ~ 6 Gyrs has $\beta = 0.241$. For comparison, a $1 M_\odot$ star in a typical Milky Way GC having an age of ~ 11 Gyrs has $\beta = 0.357$ (Claret & Gimenez 1989). A large spread of rotation speeds have been observed for MS stars in open and globular clusters, with measured values ranging from $\sim 1 - 20 \text{ km s}^{-1}$ (Mathieu & Geller 2009). A $1 M_\odot$ star having a radius of $1 R_\odot$ and a rotation speed of 2 km s^{-1} with $\beta = 0.241$ has $\Omega \sim 10^{36}$ Joules.

We let $W_i = W_i(m_i, X_i, Z_i, \tau_i)$ represent the gravitational binding energy of star i , where m_i is the star's mass, X_i is its initial hydrogen mass fraction, Z_i is its initial metallicity and τ_i is its age. For a spherical mass with a density distribution $\rho_i(r)$, the gravitational binding energy is given by:

$$\begin{aligned}
 W_i(m_i, X_i, Z_i, \tau_i) &= \frac{16\pi^2 G}{3} \int_0^{R_i} \rho_i(r) r^4 dr \\
 &= -\delta(m_i, X_i, Z_i, \tau_i) G \frac{m_i^2}{R_i},
 \end{aligned} \tag{4}$$

where the parameter δ is chosen to reflect the structure of the star and is therefore a function of its mass, age and chemical composition. For instance, a typical $1 M_\odot$ star with $(X, Z) = (0.70, 0.02)$ in an old open cluster with an age of ~ 6 Gyrs has $\delta = 1.892$. For comparison, an older but

otherwise identical star in a typical Milky Way GC with an age of ~ 11 Gyrs has $\delta = 6.337$ (Claret & Gimenez 1989). Roughly regardless of age, this gives $|W| \sim 10^{42}$ Joules for a $1 M_\odot$ star with a radius of $1 R_\odot$.

We let $U_i = U_i(m_i, X_i, Z_i, \tau_i)$ represent the total internal energy contained in star i (i.e. the star's thermal energy arising from the random motions of its particles). By solving the equations of stellar structure, the total internal energy of a purely isolated single star is uniquely determined by its mass, initial composition and age. Stars are made up of a more or less virialized fluid so that, ignoring magnetic fields, the gravitational binding energy of a star in hydrostatic equilibrium is about twice its internal thermal energy (Chandrasekhar 1939). Using this version of the virial theorem, a $1 M_\odot$ star having a radius of $1 R_\odot$ has $U \sim 5 \times 10^{41}$ Joules.

The total translational kinetic energy of object j (single, binary, triple, etc. star) is represented by T_j :

$$T_j(M_{cl}, M_j) = \frac{1}{2} M_j v_j^2, \tag{5}$$

where M_j is the total mass of the object, and v_j is its bulk translational speed. The translational velocities of stars in clusters for which energy equipartition has been achieved as a result of two-body relaxation obey a Maxwell-Boltzmann distribution, with the heaviest stars typically having the lowest velocities and vice versa (Spitzer 1987). According to the virial theorem, the root-mean-square velocity v_{rms} of the distribution depends on the total mass of the cluster M_{cl} . It follows that the velocities of stars in a fully relaxed cluster are approximately determined by their mass and the total mass of the cluster. Assuming that the typical velocity of a $\langle m \rangle$ star is roughly equal to v_{rms} , where $\langle m \rangle$ is the average stellar mass in the cluster, energy equipartition can be invoked in some clusters to approximate the translational kinetic energy, and hence velocity, of a star or binary of mass M_j :

$$v_j = \left(\frac{\langle m \rangle}{M_j} \right)^{1/2} v_{rms}. \tag{6}$$

We note that Equation 6 can only be applied in clusters for which the half-mass relaxation time is much shorter than the cluster lifetime. At the same time, the tidal truncation of the velocity distribution must not be significant. We will return to this in Section 2.2.

For a $1 M_\odot$ star with a translational speed of 1 km s^{-1} (typical of stars in old open clusters), we find $T \sim 10^{36}$ Joules. For comparison, the same star traveling at a speed of 10 km s^{-1} (typical of stars in globular clusters) has $T \sim 10^{38}$ Joules. We can put this into perspective by equating Equation 5 with Equation 4, which shows that a direct collision between two $1 M_\odot$ stars would require an impact velocity of $\sim 1000 \text{ km s}^{-1}$ in order to completely unbind the merger remnant.

The total orbital energy of orbit k is denoted ϵ_k , and is given by:

$$\epsilon_k(\mu_k, M_k, a_k) = -\frac{G\mu_k M_k}{2a_k}, \tag{7}$$

where $\mu_k = m_1 m_2 / (m_1 + m_2)$ is the reduced mass of the orbit, $M_k = m_1 + m_2$ is the total mass and a_k is the orbital semi-major axis. A binary composed of two $1 M_\odot$ stars with a period of 1000 days has $|\epsilon| = 10^{38}$ Joules. For comparison,

an otherwise identical binary with a period of 1 day has $|\epsilon| = 10^{40}$ Joules. Since most stable triples are observed to have outer periods of ~ 1000 days with close inner binaries (Tokovinin 1997; Perets & Fabrycky 2009), it follows that the total orbital energies of stable triples will be dominated by the orbital energies of their inner binaries.

After the encounter occurs, the energies that collectively define the state of the newly formed system include the rotational kinetic ($\Omega_{ii}(I_{ii}, \omega_{ii})$), thermal ($U_{ii}(m_{ii}, X_{ii}, Z_{ii}, \tau_{ii})$) and gravitational binding ($W_{ii}(m_{ii}, X_{ii}, Z_{ii}, \tau_{ii})$) energies of the stars that are left-over, as well as the total translational kinetic ($T_{jj}(m_{jj})$) and orbital ($\epsilon_{kk}(\mu_{kk}, M_{kk}, a_{kk})$) energies of any left-over stars, binaries or triples. The internal and gravitational binding energies of the left-over stars once again depend on their mass, composition and age. The mass, composition and evolutionary status of a star will decide how it responds to tidal interactions (and therefore how much tidal energy is deposited) since these are the principal factors that determine its internal structure, in particular whether or not its envelope is radiative or convective (Podsiadlowski 1996). Finally, we let Δ represent the energy lost from the system due to radiation and mass loss. We do not expect this term to be significant for the majority of the encounters we will consider since the rate of mass-loss from low-mass MS stars is small and the time-scales under consideration are relatively short compared to the lifetimes of the stars. Moreover, the velocity dispersions characteristic of the clusters we will consider are sufficiently small that we expect most collisions to have a relatively low impact velocity. Though significant mass loss can occur for high impact collisions as often occur in the Galactic centre, mass loss is only $\lesssim 5\%$ for the low impact velocity collisions expected to occur in open and globular clusters (Sills et al. 2001). Therefore, we will henceforth assume $\Delta \sim 0$.

Depending on the initial parameters of the encounter, one or more terms in Equation 1 can often be neglected. For example, given that the rotational energies of typical MS stars in both open and globular clusters are several orders of magnitude smaller than the other terms in Equation 1, we can neglect these terms for the types of encounters of interest. Even a $1 M_{\odot}$ star rotating at a rate of 100 km s^{-1} has a rotational energy of only $\sim 10^{39}$ Joules. This is considerably higher than even the highest rotation rates observed for both BSs and normal MS stars (e.g. Mathieu & Geller 2009). From this, we expect typical rotational energies to be significantly smaller than the orbital energies of even moderately hard binaries. Furthermore, Equation 5 can be combined with Equation 6 and equated to Equation 7 in order to define the hard-soft boundary for a given cluster. If a binary is hard, its initial orbital energy will outweigh its initial translational kinetic energy during typical stellar encounters (Heggie 1975). We do not expect soft binaries to survive for very long in dynamically-active clusters (Heggie 1975) (i.e. most binaries are hard), so that the translational kinetic energies of the stars, binaries and triples typically found in OCs can usually be neglected when applying Equation 1. This suggests $T_j = 0$. However, the final translational kinetic energies of the stars, binaries and triples left-over should not be neglected for encounter outcomes in which one or more stars are ejected with very high velocities. This can leave the remaining stars in a much more tightly bound configuration since stars ejected with high velocities carry off significant

amounts of energy. Finally, provided there are no very high impact collisions and tides dissipate a negligible amount of energy from the system, we also expect that:

$$\sum_i^{N_i} U_i + \sum_i^{N_i} W_i \sim \sum_{ii}^{N_f} U_{ii} + \sum_{ii}^{N_f} W_{ii}. \quad (8)$$

We can simplify our energy conservation prescription considerably for the majority of encounters occurring in old OCs. Neglecting the rotational kinetic energies of the stars, Equation 1 becomes:

$$\sum_k^{M_i} \epsilon_k(\mu_k, M_k, a_k) = \sum_{kk}^{M_f} \epsilon_{kk}(\mu_{kk}, M_{kk}, a_{kk}) + \sum_{jj}^{S_f} T_{jj}(M_{jj}) - \Delta_m, \quad (9)$$

where we have assumed $T_j = 0$ and Δ_m is the amount of energy deposited in any merger products formed during the encounter. In other words, the term Δ_m provides the required correction to Equation 8 resulting from internal energy being deposited in the merger product(s) as a result of collisions and tides. If no mergers occur or all of the orbital energy of the merging binary is imparted to the other interacting stars, $\Delta_m = 0$.

Both the total linear and angular momenta must also be conserved during any dynamical interaction. This provides two additional constraints that must also be satisfied, however the total linear and angular momenta are vector quantities that depend on the angle of approach as well as the relative orientations of the objects. As a result, there are more free parameters to fit when trying to constrain the initial parameters of an encounter using conservation of linear and angular momentum. Therefore, it is considerably more difficult to extract information pertaining to the initial orbital parameters of an encounter using conservation of momentum than it is with conservation of energy.

We have assumed that exchange interactions do not occur in applying our technique. Clearly, this assumption could be invalid for some systems. If this is the case, then our method is also invalid. This suggests that our technique is ideally suited to clusters for which the encounter time-scales are comparable to the lifetime of a typical merger product. This maximizes the probability that BSs do not experience any subsequent dynamical interactions after they are formed. Of course, most clusters of interest are unlikely to satisfy this criterion. We can assess the probability that an exchange encounter has occurred for a particular system by calculating the different encounter time-scales and comparing to the lifetime of the merger product. If the time-scales are sufficiently short, then the possibility of an exchange interaction having occurred after the system's formation must be properly addressed. We will discuss this further in Section 4.

2.2 Generalized Approach

In this section, we outline a step-by-step methodology to constrain realistic dynamical formation scenarios that could have resulted in the production of an observed stellar system containing one or more merger products. These steps are:

(i) We must first find *qualitative* constraints for the system's dynamical history and, in so doing, converge on the most probable formation scenario. The choice of formation history should be guided by the observed properties of the binary or triple system containing the merger product(s). The following guidelines can be applied to find the most probable scenario.

First, the analytic rates for single-single (1+1), single-binary (1+2), single-triple (1+3), binary-binary (2+2), binary-triple (2+3) and triple-triple (3+3) encounters can be compared to obtain a rough guide as to which of these encounter types will dominate in a given cluster. The total rate of encounters of a given type in a cluster core is well approximated by (Leonard 1989) (see Appendix A for a more generalized form for this equation):

$$\Gamma = N_0 n_0 \sigma_{gf}(v_{rel,rms}) v_{rel,rms}, \quad (10)$$

where N_0 is the number of single, binary or triple stars in the core and n_0 is the mean stellar, binary or triple number density in the core. The gravitationally-focused cross section for collision σ_{gf} is given by Equation 6 of Leonard (1989). Gravitationally-focused cross sections for the various encounter types are provided in Appendix A along with the values assumed for their pericenters.

In general, the number of single, binary and triple stars are given by, respectively, $(1 - f_b - f_t)N_c$, $f_b N_c$ and $f_t N_c$, where $N_c = 2/3\pi n_0 r_c^3$ is the total number of objects in the core (Leonard 1989), f_b is the fraction of objects that are binaries and f_t is the fraction of objects that are triples. Assuming for simplicity that v_{rel} is roughly equal for all types of encounters, the rates for two types of encounters can be compared to find the parameter space for which one type of encounter will dominate over another. These relations can be plotted in the $f_b - f_t$ plane in order to partition the parameter space for which each of the various encounter types will occur with the greatest frequency, as illustrated in Figure 1. Given a cluster's binary and triple fractions, this provides a simple means of finding the type of encounter that will occur with the greatest frequency. Our results are in rough agreement with those of Sigurdsson & Phinney (1993) who found that single-binary interactions dominate over binary-binary interactions in clusters having core binary fractions $f_b \lesssim 0.1$, and may dominate for f_b up to 0.25-0.5 in some cases.

Second, the masses of the components of an observed binary or triple system provide a lower limit for the number of stars that could have gone into its formation. The minimum number of stars that must have merged to form a given collision product, labelled $N_{min,i}$, is equal to the integer nearest to and larger than the quantity m_{rem}/m_{TO} , where m_{rem} is the mass of the merger remnant and m_{TO} corresponds to the mass of the main-sequence turn-off (MSTO). This assumes that m_{TO} has not changed significantly since the dynamical formation of the system, which should be valid provided the merger products are significantly more massive than the turn-off so that their lifetimes are relatively short. The number of stars that went into an encounter N_i must therefore satisfy:

$$N_i \geq \sum_i^M N_{min,i} + M_0, \quad (11)$$

Figure 1. Plot showing the parameter space in the $f_b - f_t$ plane for which each of the various encounter types dominate. Boundaries between regions are indicated by solid lines, each segment of which is obtained by equating two particular encounter rates using Equation 10 and the relevant cross sections derived using Equation 6 of Leonard (1989). We assume $a_t = 5a_b$ and $a_b = 90R$ in obtaining the relations between encounter rates. This is a reasonable choice for the ratio between the average binary and triple geometric cross sections given that the ratio between the outer and inner orbital semi-major axes of triples must be relatively large (by a factor of $\gtrsim 10$) in order for them to be stable (Mardling 2001).

where M_0 is the number of normal stars (i.e. not formed from mergers) and M denotes the number of merger products.

Third, an estimate for the average stellar mass, and therefore the masses of typical stars expected to undergo encounters, should be guided by a realistic stellar mass function for the host cluster. First of all, observations have shown that a significant depletion of low-mass stars occurs in dynamically evolved clusters (i.e. those for which $t_{rh} \ll t_{age}$, where t_{rh} is the half-mass relaxation time and t_{age} is the cluster age) since they are preferentially ejected from the cluster during close encounters (e.g. von Hippel & Sarajedini 1998; Bonatto, Bica & Santos 2005; De Marchi, Paresce & Portegies Zwart 2010). This suggests that OCs and the least massive Milky Way GCs should have stellar mass functions that, at least in their central cluster regions, appear eroded at the low-mass end. From this, we expect $\langle m \rangle \lesssim m_{TO}$. Finally, most of the stars involved in dynamical encounters should have masses close to or even slightly greater than the average stellar mass $\langle m \rangle$. This is because gravitational focusing is strongest for the most massive objects, contributing to a shorter encounter time-scale.

Finally, the most likely formation scenario will, strictly speaking, minimize the total or cumulative encounter time-scale. However, the total time-scale required for a dynamical formation scenario that involves more than one encounter

will typically be dominated by the second encounter. This is because, after an initial encounter has occurred between any two suitable objects to form a new stellar configuration, the time-scale for a second encounter to occur is given by the time required for the product of the initial encounter to experience a subsequent encounter. *This increases the encounter time-scale by a factor N_0 .* In other words, Equation 10 provides the time required for *any* two of the specified objects to experience an encounter (two binaries, a binary and a triple, etc.). It can be multiplied by N_0 to obtain an estimate for the time required for a *specific* object to experience an encounter. For example, to find the time required for a specific binary to experience an encounter with another single, binary or triple star, we must multiply by a factor $f_b N_c$. It follows that the timescale for multiple encounters to occur is considerably longer than any of the single encounter timescales. Therefore, unless the number of either binary or triple stars is very low, scenarios involving the fewest number of encounters are generally preferred since this tends to minimize the total time required for the encounter(s) to occur in a realistic cluster environment.

The times *between* the various types of encounters can be derived using Equation 10 and have been provided in Appendix A. These time-scales can be multiplied by $(1 - f_b - f_t)N_c$, $f_b N_c$ or $f_t N_c$ to find the time required for a *particular* single, binary or triple star, respectively, to encounter another object. This yields time-scales that are in rough agreement with Equation 8-125 of Binney & Tremaine (1987). As an example, we can multiply Equation A8 by $f_b N_c$ to find the time for a particular binary to experience an encounter with another binary. This gives:

$$\tau_{2+2}^b = 2.7 \times 10^{10} f_b^{-1} \left(\frac{10^3 \text{ pc}^{-3}}{n_0} \right) \left(\frac{v_{rms}}{5 \text{ km/s}} \right) \left(\frac{0.5 M_\odot}{< m >} \right) \left(\frac{1 \text{ AU}}{a_b} \right) \text{ years}, \quad (12)$$

Provided the derived encounter time-scale is shorter than the lifetime of the merger product(s), this suggests that the encounter scenario in question could be realistic and is therefore a candidate formation history. Conversely, if the derived encounter time-scale is longer than the lifetime of the merger product(s), then the dynamical formation history is unlikely to have actually occurred. In general, the shorter the derived encounter time-scale, the more likely it is that one or more such encounters actually took place within the lifetime of the merger product(s).

The preceding guidelines specify a narrow range of allowed formation scenarios. In particular, they constrain the number of stars involved in the encounter(s), the types of objects (i.e. single, binary or triple stars) involved, and the number of encounters that took place. In most cases, these guidelines will converge on a single qualitative formation history that is unique up to the possible initial distribution of energies that describe suitable interactions.

(ii) Next, we must assign an approximate value based on the observations to every parameter possible in Equation 1. Nearly all of the required information pertaining to the final distribution of energies in Equation 1 can be found from spectroscopy alone, though repeated measurements spread out over a sufficiently long timeline will typically be required to obtain orbital solutions and to detect outer triple companions whenever they are present. This gives the final orbital

energies ϵ_{kk} as well as the gravitational binding energies W_{ii} of the stars according to Equation 7 and Equation 4, respectively. Since merger products have been shown to typically be in hydrodynamic equilibrium (e.g. Sills et al. 2001), the stars' internal energies U_{ii} can then be approximated using the virial theorem. Alternatively, stellar models can be used together with photometry.

The measured broadening of spectral lines gives an estimate for the stars' rotation speeds (although there is a strong dependence on the angle of inclination of the stars' axis of rotation relative to the line of sight), which in turn provides their rotational kinetic energies Ω_{ii} according to Equation 2. In conjunction with proper motions, radial velocity measurements also provide an estimate for the systemic velocity of the final stellar configuration relative to the cluster mean, which in turn gives its translational kinetic energy T_{jj} according to Equation 5. Finally, the cluster velocity dispersion provides an estimate of the relative velocity at infinity for a typical encounter, which in turn decides the initial translational kinetic energies T_j of stars or binaries involved in the encounter. Under the assumption of energy equipartition for both single and binary stars, the initial velocities of the impactors can be approximated by Equation 6. The assumption of energy equipartition should be valid in clusters for which the half-mass relaxation time is considerably shorter than the cluster lifetime, and this is the case for most GCs (Harris 1996; De Angeli et al. 2005). On the other hand, this assumption is likely invalid for most open clusters. This is because the tidal truncation of the velocity distributions are significant in OCs since they are much less centrally concentrated. In this case, the initial velocities of the impactors can be approximated from the velocity dispersion, which is nearly independent of mass.

(iii) We can now obtain *quantitative* constraints for the initial encounter(s). Once we have decided on a qualitative encounter scenario that could have produced the observed merger product(s), we can estimate the orbital energies of the initial binaries or triples going into the encounter using Equation 9. This gives us an equation that relates the initial orbital semi-major axes of all orbits going into the encounter (to each other). If only one orbit goes into the encounter, then we can solve for it explicitly. From this, we can constrain the initial collisional cross sections for realistic encounters. If the derived cross section is significantly smaller than the average semi-major axes of all binaries and/or triples in the cluster, then we can infer that the time required for the encounter to occur is significantly longer than the corresponding time-scale given in Appendix A. If we use our derived cross section found from Equation 9 instead of this average semi-major axis, this should give us an idea of the time required for that particular type of encounter to occur. Strictly speaking, however, this is only a rough approximation since these are typical time-scales found using the average period (or, equivalently, semi-major axis and hence cross section).

If we find that the derived encounter time-scale is longer than the lifetime of a typical merger product, then the chosen formation history is unlikely to have actually occurred. In this case, it becomes necessary to re-evaluate the possible dynamical formation histories of the observed binary or triple system, choosing the next most likely qualitative scenario for further quantitative analysis. These steps can be

repeated until either a suitable formation history is found or the list of possibilities is exhausted so that the only remaining conclusion is that the observed binary or triple system is unlikely to have a dynamical origin.

3 RESULTS

In this section, we apply our technique to two particular cases of observed binaries and triples containing merger products. The first is an observed triple system in the old open cluster M67 that is thought to contain two BSs (van den Berg et al. 2001; Sandquist et al. 2003). The second is the period-eccentricity distribution of the BS binary population of the OC NGC 188, which bears a remarkable resemblance to M67 (Mathieu & Geller 2009). After determining the most probable qualitative formation scenarios, we obtain quantitative constraints for suitable initial conditions that could have produced the observed orbital parameters.

3.1 The Case of S1082

S1082 is believed to be a triple system in the old OC M67 (van den Berg et al. 2001; Sandquist et al. 2003). The observations suggest that a distant triple companion orbits a close binary containing a BS and another peculiar star. The companion to the BS has a photometric appearance that puts it close to the MSTO in the CMD and yet, curiously, its derived mass is significantly greater than that of the turn-off. The outer companion is a BS in its own right, so that S1082 is thought to be composed of two BSs. Although both the inner and outer components of this suspected triple have systemic velocities that suggest they are both cluster members, it is important to note that there is no direct evidence proving a dynamical link between the two (Sandquist et al. 2003). Assuming for the time being that a dynamical link does exist, we can apply the procedure outlined in Section 2.2 to the case of S1082:

(i) Before applying our technique, it is important to convince ourselves that a dynamical origin is possible for the observed system. This is certainly the case for S1082 since no known BS formation mechanism could have produced the observed stellar configuration without at least some help from dynamical interactions. The first step of our procedure is to find qualitative constraints and, in so doing, isolate the most probable encounter scenario.

First, we need to know the cluster binary and triple fractions in order to use Figure 1 to find the encounter type occurring with the greatest frequency. From this, we find that 2+2 encounters presently dominate in M67. Fan et al. (1996) showed that observations of M67 are consistent with a cluster multiple star fraction $\sim 50\%$. More recent studies report a lower limit for $f_b + f_t$ that is consistent with their results (e.g. Latham 2005; Davenport & Sandquist 2010). Radial velocity surveys and simulations of dynamical interactions suggest that old OCs like M67 are likely to host a number of triples with outer periods $\lesssim 4000$ days (e.g. Latham 2005; Ivanova et al. 2008). We assume $f_t/f_b \sim 0.1$ and, using the result of Fan et al. (1996), this gives $f_b \sim 0.45$ and $f_t \sim 0.05$. Our assumed ratio f_t/f_b is slightly lower than

found for the field, or $f_t/f_b \sim 0.2$ (Eggleton & Tokovinin 2008).

Second, we need to constrain the number of stars that went into the encounter. The mass of the MSTO in M67 is estimated to be $\sim 1.3 M_\odot$ (Mathieu & Geller 2009). The total mass of S1082 is $\sim 5.8 M_\odot$ (Sandquist et al. 2003). From Equation 11, its formation must therefore have involved at least 5 stars.

At this point, we can conclude that a single 2+2 encounter could not have produced S1082 since this scenario involves only 4 stars and we know that at least 5 stars are needed. We must therefore consider either a single 2+3 or 3+3 encounter, or a multiple encounter scenario. In order to isolate the most probable of these possibilities, we must calculate and compare their encounter time-scales. To do this, we require estimates from the observations for a few additional cluster parameters. For M67, the core radius is $r_c \sim 1.23$ pc (Bonatto, Bica & Santos 2005; Giersz, Heggie & Hurley 2008). From this and the central velocity dispersion, we can calculate the central mass density using Equation 4-124b of Binney & Tremaine (1987), which gives $\rho_0 \sim 10^{1.9} M_\odot \text{pc}^{-3}$. The central stellar number density can then be approximated according to:

$$n_0 = \frac{\rho_0}{\langle m \rangle \frac{M}{L}}, \quad (13)$$

where M/L is the cluster mass-to-light ratio and should be around 1.5 for an OC as old as M67 (e.g. De Grijs et al. 2008). We take $f_t \sim 0.05$ and assume most stable triples have outer periods of $P \sim 1000$ days so that $a_t \sim 3$ AU (assuming all three stars have a mass of $1 M_\odot$). We also take $f_b \sim 0.45$ and assume an average binary period of $P \sim 100$ days so that $a_b \sim 0.6$ AU (assuming both components have a mass of $1 M_\odot$). We assume an average stellar mass of $\langle m \rangle \sim 1.0 M_\odot$, which is in reasonable agreement with the observations (Girard et al. 1989). Assuming that the average mass of merger remnants is equal to $2 \langle m \rangle$ and extrapolating the results of Sills et al. (2001) for solar metallicity and more massive parent stars, we will assume that the typical lifetime of a merger product is $\tau_{BS} \sim 1.5$ Gyrs.

A comparison of the relevant encounter time-scales suggests that the most probable dynamical formation scenario for S1082 is a single 2+3 encounter, although a single 3+3 encounter is almost equally as probable. Given our assumptions, we find 8.9×10^8 years and 3.3×10^9 years for the times between 2+3 and 3+3 encounters, respectively, in the core of M67. From this, we expect approximately two and zero 2+3 and 3+3 encounters, respectively, to have occurred within the last τ_{BS} years.

From Equation 12, we find that the time for a particular binary to encounter another binary is 7.3×10^{10} years. Similarly, the time for a particular quadruple to encounter another binary is 8.9×10^9 years (using Equation 12 and assuming the quadruple has a mass of $4 \langle m \rangle$ and its geometric cross section is twice as large as the average outer semi-major axis of triples). Since these time-scales are considerably longer than the cluster lifetime, this suggests that a formation scenario for S1082 involving back-to-back 2+2 encounters is unlikely, even if the second encounter occurred sufficiently soon after the first that all four stars comprising the initial pair of interacting binaries are still gravitation-

ally bound. If we replace one of the 3 binaries involved in this scenario with a triple system, the total encounter time remains longer than the cluster lifetime.

(ii) Before more quantitative constraints can be found, we must refer to the literature in order to obtain estimates for every term in Equation 9. The observations suggest that a binary system composed of a $2.52 M_{\odot}$ blue straggler (component Aa) and a $1.58 M_{\odot}$ MS star (component Ab) has a period of $P \sim 1.068$ days (van den Berg et al. 2001). There is also evidence for a $1.7 M_{\odot}$ blue straggler companion (component B) that acts as a stable outer triple with a period of $P \sim 1188.5$ days (Sandquist et al. 2003). From this, we can calculate the final orbital energies (ϵ_A and ϵ_B) of the triple:

$$|\epsilon_A| + |\epsilon_B| \sim |\epsilon_A| \sim 10^{41} J, \quad (14)$$

where we have used the fact that $|\epsilon_A| \gg |\epsilon_B|$ since $|\epsilon_B| \sim 10^{39} J$. It is important to note that these peculiar stars are often underluminous, so the inferred mass of the tertiary companion should be taken with caution (van den Berg et al. 2001).

The systemic radial velocity of the system is 33.76 ± 0.12 km/s (Sandquist et al. 2003). Although this only provides us with an estimate for the systemic velocity of S1082 in one dimension, it is consistent with the cluster mean velocity of 33.5 km/s. Therefore, the available knowledge for the systemic velocity of S1082 is consistent with its final translational kinetic energy being negligible. From this, we take $T_{A,B} \sim 0$. The central velocity dispersion in M67 is only 0.5 km s^{-1} (Mathieu & Latham 1986; Mathieu et al. 1990). This suggests that the relative velocity at infinity, and therefore the typical impact velocities of collisions, should be small compared to the significant orbital energy of component A in S1082 (and any very hard binaries that went into the encounter). From this, we take $\Delta_m \sim 0$.

(iii) We are now ready to obtain quantitative constraints for the formation of S1082. We can use Equation 9 since M67 is an old OC with a small central velocity dispersion so that the assumptions used to derive this equation are valid. At this point, we must consider the details of our chosen formation scenario more carefully in order to choose a set of initial conditions that will satisfy Equation 9 as well as reproduce the observed parameters of S1082. In doing so, we find that it is not possible to form S1082 with a single 2+3 encounter. This is because 5 stars with masses $m < m_{TO}$ are insufficient to form both an inner binary with a total mass $\sim 4.1 M_{\odot}$ and an outer tertiary companion with a mass $1.7 M_{\odot}$. That is, the total mass of the inner binary is larger than three times the mass of the MSTO so that its formation must have involved four or more stars.

A single 3+3 encounter is therefore the most probable formation scenario for S1082. Although there are a number of ways we can reproduce the observed parameters of S1082 with a 3+3 encounter, including the component masses, we must use Equation 9 to identify the most probable of these scenarios. To do this, we can solve for the initial orbital energies of all binaries and/or triples going into the encounter, which will in turn constrain their initial semi-major axes and therefore cross sections for collision. In applying Equation 9, we are only concerned with the initial and final orbital energies of the inner binaries of the triples. This is because the orbital energies of any outer triple companions will be significantly outweighed by the orbital energies of their inner

binaries. It follows that the contribution from the outer orbital energies of triples to the total energy of the encounter will be negligible.

From Equation 9, we find that the formation of S1082 should have involved at least one hard binary with $|\epsilon_i| \sim 10^{41} J$ whose components did not merge (with each other) during the encounter in order to account for the significant orbital energy of component A. This need not be the case, however, if one or more stars were ejected from the system with an escape velocity of $\gtrsim 100$ km/s. Of course, this would require an increase in the total number of stars involved in the interaction and therefore a single encounter scenario involving 7 or more stars, and hence one or more quadruple systems. Although very few observational constraints for the fraction of quadruple systems in clusters exist, this seems unlikely.

The orbital energies of the inner binaries of the two triples initially going into the encounter should both be on the order of $10^{41} J$. Although we have found that only one hard binary with $|\epsilon_i| \sim 10^{41} J$ is required, triples are only dynamically stable if the ratio of their inner to outer orbital periods is large (roughly a factor of ten or more) (e.g. Mardling 2001). We do not expect very wide binaries to survive for very long in dense cluster environments, which suggests that the inner binary of every triple is very hard. We expect from this that these inner binaries should, to within an order of magnitude, all have roughly the same orbital energy.

The presence of outer triple companions is required in order for most very hard binaries to actually experience encounters within the lifetime of a typical merger product. Assuming masses of $1 M_{\odot}$ for both components, an orbital energy of $10^{41} J$ corresponds to a period ~ 0.4 days, or a semi-major axis ~ 0.02 AU. Therefore, the cross section for collision for a 2+2 encounter in which both binaries are very hard is smaller than the average cross section for a 2+2 encounter (found from the observed binary period distribution) by a factor of ~ 30 . This suggests that the time required for an encounter to occur between two very hard binaries is considerably longer than the cluster lifetime. This is not the case if the hard binaries have triple companions, however, since the outer orbit significantly increases the collisional cross section and hence decreases the encounter time-scale.

Energy conservation also suggests that if S1082 did form from a single 3+3 encounter, it is likely that the close inner binaries of the two triples collided directly. If two separate mergers then subsequently occurred during this interaction, this could have reproduced the observed orbital parameters of the close inner binary of S1082 (component A). The formation of the outer triple companion is more difficult to explain via a single 3+3 encounter since it also appears to be the product of a stellar merger. Nonetheless, if the outer companions of both triples undergoing the encounter end up orbiting the interacting (or merged) pair of close inner binaries at comparable distances, it is possible that their orbits would overlap as a result of gravitational focussing. Although this seems unlikely, it could produce a blue straggler of the right mass and orbital period to account for component B. We will return to this possibility in Section 4.

Even though the analytic estimates presented here are only approximate, they serve to highlight the low probability of a system such as S1082 having formed dynamically in

M67. Based on our results, the most likely formation scenario for S1082 is a single 3+3 encounter, although we expect very few, if any, to have occurred in the lifetime of a typical merger product. This need not be the case, however, provided M67 had a higher central density in the recent past since this would increase the total encounter frequency. This will be discussed further in Section 4.

3.2 The Period-Eccentricity Distribution of the Blue Straggler Binary Population in NGC 188

Mathieu & Geller (2009) found 21 blue stragglers in the old open cluster NGC 188. Of these, 16 are known to have a binary companion. Orbital solutions have been found for 15 of these known BS binaries. From this, Mathieu & Geller (2009) showed that the BS binary population in NGC 188 has a curious period-eccentricity distribution, with all but 3 having periods of ~ 1000 days. Of these three, two have periods of $\lesssim 10$ days (binaries 5078 and 7782). Interestingly, one of these short-period BS binaries has a non-zero eccentricity. The normal MS binary population, on the other hand, shows no sign of a period gap for $10 \lesssim P \lesssim 1000$ days (Mathieu & Geller 2009). We can apply the procedure outlined in Section 2.2 to better understand how we expect mergers formed during dynamical encounters to contribute to the BS binary population in NGC 188. Although the method described in Section 2.2 treats one system at a time, we will apply our technique to the BS binary population of NGC 188 as a whole.

(i) Before applying our technique, we must satisfy ourselves that a dynamical origin is possible for a large fraction of the observed BS population. Several examples of evidence in favour of a dynamical origin exist. For one thing, most BSs in NGC 188 have been found to have binary companions (Mathieu & Geller 2009). This should not be the case if most BSs are the products of the coalescence of isolated binary systems. On the other hand, a binary companion should be expected if the BSs were formed from mass transfer. However, the results of Chen & Han (2008b) could suggest that most of the BSs in NGC 188 were not formed from mass transfer alone, providing indirect evidence that many BSs were formed from mergers. A binary companion should also be expected if the coalesced binary had a tertiary companion to begin with. Although the Kozai mechanism can act to decrease the orbital separation of the inner binary of a triple, an additional perturbation is often required in order to fully induce the binary to merge (Perets & Fabrycky 2009). All of this suggests that dynamical interactions likely played at least some role in the formation of a significant fraction of the BS binary population in NGC 188.

The first step of our technique is to find the most commonly occurring type(s) of encounter(s). Geller et al. (2008) found a completeness-corrected multiple star fraction $f_b + f_t \sim 0.27$ out to a period of ~ 4000 days. This represents a lower limit since it does not include binaries with $P \gtrsim 4000$ days. Using the same lower limit for the ratio $f_t/f_b \sim 0.1$ found by Latham (2005), Figure 1 suggests that 1+2 encounters should currently dominate in NGC 188.

Second, we must constrain the minimum number of stars required to form the observed systems. From this, we can show that a merger occurring during all but a 1+1 encounter

could produce a BS in a binary since this is the only type of encounter that involves less than 3 stars. By dividing the total mass of an observed system by m_{TO} , we can find an estimate for the minimum number of stars required to have been involved in its formation. Since all but one BS binary contain only a single merger product with a mass $\geq m_{TO}$, realistic dynamical formation scenarios for these systems require 3 or more stars. Binary 7782, on the other hand, is thought to contain two BSs so that if its formation involved two separate mergers it must have required 4 or more stars.

A more quantitative comparison of the different encounter types is required since we do not yet know if *enough* encounters occurred in the last τ_{BS} years to account for all 16 observed BS binaries. To do this, we require estimates from the observations for a few additional cluster parameters in order to calculate and compare the relative encounter time-scales. NGC 188 has been found to have a central density of $\rho_0 = 10^{2.2} L_\odot \text{ pc}^{-3}$ (Sandquist et al. 2003) and a core radius of $r_c \sim 1.3$ pc (Bonatto, Bica & Santos 2005). We found an average stellar mass for the cluster of $\langle m \rangle \sim 0.9 M_\odot$. This was done by determining the cluster luminosity function using only those stars known to be cluster members from the proper-motion study of Platais et al. (2003). With this, a theoretical isochrone taken from Pols et al. (1998) was used to determine the cluster mass function and the average stellar mass was calculated.

A sufficient number of suitable dynamical interactions should have occurred in the last τ_{BS} years for the formation of every BS binary in NGC 188 to have been directly mediated by the cluster dynamics. Assuming once again that $\tau_{BS} \sim 1.5$ Gyrs, the encounter time-scales derived in Appendix A suggest that a minimum of nine, eight, eight, three and one 1+2, 2+2, 1+3, 2+3 and 3+3 encounters, respectively, occurred within the lifetime of a typical merger product. It follows that at least ~ 29 dynamical encounters should have occurred in NGC 188 in the last τ_{BS} years. Of these 29 encounters, 12 should have involved triples. In deriving these time-scales, we have taken $f_b + f_t \sim 0.27$ from Geller et al. (2009) and have adopted the same ratio $f_t/f_b \sim 0.1$ as found for M67. Consequently, these represent lower limits for f_b and f_t , so that our derived encounter rates are also lower limits. We have also assumed an average outer semi-major axis for triples of $a_t \sim 3$ AU (corresponding to a period of ~ 1000 days for a binary composed of two $1 M_\odot$ stars).

(ii) The next step is to apply our energy conservation prescription to the observed BS population. This will allow us to constrain the orbital energies of typical binaries or triples expected to form BS binaries via dynamical interactions. First, we must refer to the literature in order to obtain estimates for every term in Equation 9. From the observed BS period-eccentricity distribution in NGC 188, we know that most BS binaries have periods of ~ 1000 days (we will call these long-period binaries), although there are a couple with very short periods of ~ 10 days (which we will call short-period binaries). This provides an estimate for the final orbital energies ϵ_{kk} of BS binaries formed during dynamical interactions. Specifically, we find $|\epsilon_{kk}| \sim 10^{39}$ J and $|\epsilon_{kk}| \sim 10^{40}$ J for the final absolute orbital energies of the long- and short-period BS binaries, respectively.

Every BS in NGC 188 with a high cluster membership probability has both radial and proper motion velocities

that, to within their respective uncertainties, are consistent with the observed central velocity dispersion of $\sigma_0 = 0.41 \text{ km s}^{-1}$ (Platais et al. 2003; Geller et al. 2008; Geller et al. 2009). From this, we assume that the final translational kinetic energies of any binaries or triples formed from dynamical interactions will be negligible, or $T_{jj} \sim 0$. As for M67, we assume $\Delta_m \sim 0$ since we expect low impact velocities for collisions as a result of the low velocity dispersion in NGC 188.

(iii) We are now equipped with estimates from the literature that will allow us to obtain quantitative constraints for specific encounter scenarios. In particular, we can use Equation 9 to constrain the initial orbital energies of all binaries and/or triples going into an encounter. We can also constrain the specific details of interactions for which the encounter outcome reproduces the observed parameters of the BS binary. We will consider energy conservation separately for two different classes of BS binaries, namely short- and long-period.

The short-period BS binaries have large (absolute) orbital energies. Equation 9 suggests that this energy requires that at least one hard binary was involved in the encounter. Alternatively, an encounter which involved only softer binaries must have resulted in at least one star escaping with a significant velocity ($\gtrsim 100 \text{ km/s}$). However, in order to produce a merger product in a short-period binary, encounters involving triples are the most favoured. Binary-binary (and especially 1+2) encounters which involve at least one hard binary will have smaller cross sections for collision than those encounters involving wide binaries. But energy conservation suggests that 2+2 encounters involving wide binaries are unlikely to produce a merger product in a close binary. Stable triples, on the other hand, contain a hard inner binary (Mardling 2001) which will naturally account for the large orbital energy of the resulting BS binary. Stable triples also have a large cross section for collision because of the wide orbit of the tertiary companion. The times between 1+2, 2+2 and 1+3 encounters are all comparable, suggesting that most encounters involving hard binaries are 1+3 encounters.

The short-period BS binaries could have formed from a direct stellar collision that occurred within a dynamical encounter of a hard binary and another single or (hard) binary star (we call this Mechanism I). If at least one of the objects going into the encounter was a triple, then four or more stars were involved in the interaction. Therefore, if binaries 5078 and 7782 were formed from this mechanism, they could possess triple companions with sufficiently long periods that they would have thus far evaded detection. This is consistent with the requirements for both conservation of energy and angular momentum. Interestingly, the presence of an outer triple companion could also contribute to hardening these BS binaries via Kozai cycles operating in conjunction with tidal friction (Fabrycky & Tremaine 2007). In this case, Equation 1 shows that tides can contribute to making a binary's orbital energy more negative by depositing internal energy into the component stars.

Although 2+2 encounters should also contribute to the observed BS population, most of these should occur between a short-period binary and a long-period binary. This is because most encounters resulting in mergers involve very hard binaries and binaries with long periods have large cross sec-

tions for collision and therefore short encounter times. Equation 9 indicates that the minimum period of a BS binary formed during a 2+2 encounter is usually determined by the orbital energy of the softest binary going into the encounter. This is because the most likely merger scenario is one for which the hard binary is driven to coalesce by imparting energy and angular momentum to other stars involved in the interaction (Fregeau et al. 2004). Assuming most of this energy is imparted to only one of the stars causing it to escape the system, we can take Δ_m in Equation 9 to be very small and the orbital energy of the left-over BS binary will be comparable to the orbital energy of the initial wide binary going into the encounter. As more energy is imparted to the star left bound to the merger product over the course of the interaction, its final orbital separation effectively increases. This in turn contributes to an increase in the final orbital energy of the left-over BS binary. Finally, from Equation A8, the period of the initial wide binary should be relatively long (roughly $\gtrsim 1000$ days) since the contribution from the very hard binary to the total cross section for collision is negligible. Otherwise, the time required for such a 2+2 encounter to occur could exceed τ_{BS} .

Now let us consider the long-period BS binaries in NGC 188. Based on Equation 9, we expect encounters involving 3 or more stars and only one very hard binary to typically produce long-period BS binaries if the hard binary is driven to merge during the encounter. This is because the hard binary merges so that its significant (negative) orbital energy can only be re-distributed to the other stars by giving them positive energy. Since the only other orbits involved in the interaction are wide, the left-over BS binary should also have a wide orbit. Alternatively, BSs formed during interactions involving more than one very hard binary should be left in a wide binary provided enough energy is extracted from the orbit of the binary that merges. In this case, a significant fraction of this energy must be imparted to the other stars in order to counter-balance the significant orbital energy of the other very hard binary. If not, the other short-period binaries are required to either merge or be ejected from the system. Otherwise Equation 9 suggests that the left-over BS binary should be very hard. However, it is important to recall that we are neglecting other non-dynamical mechanisms for energy extraction. We will return to this last point in Section 4.

In order to help us obtain more quantitative estimates for the long-period BS binaries, consider two additional mechanisms for mergers during dynamical interactions that involve both short- and long-period orbits. First, a merger can occur if a sufficient amount of orbital energy is extracted from a hard binary by other interacting stars (called Mechanism IIa). Alternatively, a merger can occur if the encounter progresses in such a way that the eccentricity of a hard binary becomes sufficiently increased that the stellar radii overlap, causing the stars to collide and merge (called Mechanism IIb). In the case of Mechanism IIb, most of the orbital energy of the close binary must end up in the form of internal and gravitational binding energy in the merger remnant after the majority of its orbital angular momentum has been redistributed to the other stars (and tides have extracted orbital energy). In the case of Mechanism IIa, however, most of the orbital energy of the close binary must be imparted to one or more of the other interacting stars in the form of bulk

kinetic motion. Consequently, one or more stars are likely to obtain a positive total energy and escape the system. This need not necessarily be the case for 2+3 and 3+3 encounters provided the second hardest binary orbit involved in the interaction has a sufficiently negative energy.

Regardless of the type of encounter, Equation 9 shows that the extraction of orbital energy from a hard binary in stimulating it to merge should increase the final orbital period of a BS binary. To illustrate this, we will consider 1+3 encounters since the predictions of energy conservation are nearly identical for the other encounter types of interest. Moreover, we have shown that encounters with triples are the most likely to involve very hard binaries. Equation 9 can be re-written for 1+3 encounters:

$$\epsilon_{12,4} = \epsilon_{12,3} - f_{12} \times \epsilon_{12}, \quad (15)$$

where we have assumed that stars 1 and 2 comprise the initial hard inner binary of the triple, star 3 is the initial outer triple companion and star 4 is the interloping single star. Stars 1 and 2 are assumed to merge during the encounter by exchanging energy and angular momentum with stars 3 and 4. We further assume that enough energy is imparted to star 3 that it escapes the system. We let f_{12} represent the fraction of energy extracted from the orbital energy of the hard inner binary of the triple in the form of bulk kinetic motion by star 4. Since the remaining orbital energy of the close inner binary will end up in the form of internal and gravitational binding energy in the merger remnant, we have assumed $(1 + f_{12}) \times \epsilon_{12} \sim T_3 - \Delta_m$ in obtaining Equation 15 from Equation 9.

This formation mechanism could leave the BS as a single star if f_{12} exceeds a few percent. As shown in Figure 2, the period of a BS binary formed during a 1+3 encounter via Mechanism IIa ($P_{12,4}$) is only slightly smaller than the period of the outer orbit of the triple initially going into the encounter ($P_{12,3}$). This assumes, however, that no energy is exchanged between the hard inner binary and star 4 (i.e. $f_{12} = 0$). The predictions from energy conservation for this case are therefore identical for Mechanism IIb. In general, as the amount of energy extracted from the hard inner binary of the triple by star 4 increases, so too does the rate at which $P_{12,4}$ increases with increasing $P_{12,3}$. If the amount of energy extracted is $\gtrsim 5\%$ of the orbital energy of the initial inner binary of the triple, $P_{12,4}$ becomes a very steeply increasing function of $P_{12,3}$.

Interestingly, the two general qualitative merger scenarios described above (Mechanisms I and II) naturally create a bi-modal period distribution similar to the period gap observed for the BS binaries if we assume that 1+3 encounters produced these objects. To illustrate this, Figure 3 shows a histogram of periods for 15 BS binaries formed during 1+3 encounters via these two generic merger scenarios. In order to obtain this plot, we have used the observed period-eccentricity distribution for the regular MS-MS binary population in NGC 188 from Geller et al. (2009) to obtain estimates for the orbital energies of any binaries and/or triples going into encounters. Specifically, in order to obtain periods for the outer orbits of triples undergoing encounters, we randomly sampled the regular period distribution, including only those binaries with periods satisfying $400 \text{ days} < P < 4000 \text{ days}$. We have shown that the initial outer orbits of triples going into 1+3 encounters provide a rough

Figure 2. Plot showing the typical periods of BS binaries formed from 1+3 encounters in which the hard inner binary of the triple merges. As described in the text, the period of the BS binary formed during the interaction is denoted $P_{12,4}$ and corresponds to the y-axis, whereas the period of the outer orbit of the triple initially going into the encounter is denoted $P_{12,3}$ and corresponds to the x-axis. The lower straight line corresponds to the case where no energy was extracted from the inner binary of the triple by star 4 (i.e. $f_{12} = 0$). As the amount of energy extracted increases, however, so too will the rate at which $P_{12,4}$ increases with increasing $P_{12,3}$. Cases where $f_{12} = 0.005$, $f_{12} = 0.01$, $f_{12} = 0.02$, $f_{12} = 0.03$ and $f_{12} = 0.04$ are shown as lines of increasing slope.

lower limit for the periods of BS binaries formed via Mechanism II. Therefore, any BS binaries formed in this way could only have been identified as binaries by radial velocity surveys if the triple going into the encounter had a period < 4000 days (since this corresponds to the current cut-off for detection). All triples are taken to have a ratio of 30 between their inner and outer orbital semi-major axes. This ratio has been chosen to be arbitrarily large enough that the triples should be dynamically stable, however we will return to this assumption in Section 4.

We will adopt a ratio based on the observations of Mathieu & Geller (2009) for the fraction of outcomes that result in each of these two possible merger scenarios. In particular, if we assume that the three BS binaries with $P < 150$ days were formed via Mechanism I whereas the other 12 were formed via Mechanism II (either IIa or IIb since energy conservation predicts similar periods for the left-over BS binaries), this would suggest that Mechanism II is ~ 4 times more likely to occur than Mechanism I during any given 1+3 encounter. We will return to this assumption in Section 4.

As a result of the requirement for conservation of angular momentum, we would expect to see a large spread in the distribution of eccentricities for BSs in long-period binaries formed from encounters involving triples. This is because conservation of momentum requires that the total momen-

Figure 3. Histogram of the period distribution (in days) expected for BS binaries formed during 15 1+3 encounters. The parameter space assumed for the encounters is described in the text. The stars show the observed BS binary period distribution in NGC 188 taken from Mathieu & Geller (2009), where each star represents a single BS binary.

tum going into the encounter must be equal to the total momentum left over after the interaction. However, the total initial momentum depends not only on the initial orbital eccentricities of any binaries or triples going into the encounter, but also the relative orientations and trajectories of the colliding objects. Since the relative orientations and trajectories are random, the final eccentricities of the BS binaries can take on a range of values. In other words, we cannot predict the final distribution of momenta for BS binaries formed from dynamical encounters. However, the observed BS binaries in NGC 188 are observed to have a range of eccentricities and this is not inconsistent with a dynamical origin involving triples.

BSs in short-period binaries formed via Mechanism I can also end up with just about any eccentricity immediately after the encounter for the same reasons outlined above. However, tidal effects become increasingly significant with decreasing orbital separation so that the hardest binaries should typically circularize the fastest. Although theoretical estimates for the rate of tidal circularization are uncertain (Meibom et al. 2005), the circularization cut-off period is estimated to be ~ 15 days in NGC 188 (Mathieu et al. 2004). From this, it is entirely possible that recently formed BS binaries with $P \sim 10$ days have not yet become fully circularized.

4 SUMMARY & DISCUSSION

In this paper, we have presented a generalized analytic prescription for energy conservation during stellar encoun-

ters. Our method can be used to identify the most probable dynamical formation scenario for an observed binary or triple system containing one or more merger products. We have shown that, using the observed orbital parameters of the system, the allowed initial orbital semi-major axes of any binary or triple systems involved in its formation can be constrained. The initial semi-major axes of the orbits in turn provide an estimate for the collisional cross section and therefore the time-scale for the encounter to occur in its host cluster. In order to apply our technique, repeated spectroscopic measurements of the binary or triple system containing the merger product(s) are needed in order to obtain its orbital solution and systemic velocity. However, the time-scales provided in Appendix A can still be applied if only the fraction of binary and triple stars are known, which can be determined either spectroscopically (e.g. Mathieu et al. 1990; Latham 2005) or photometrically (e.g. Fan et al. 1996).

As we have shown, consideration of the requirement for energy conservation is ideal for identifying trends during stellar encounters, whereas numerical scattering experiments can require hundreds or even thousands of simulation runs before patterns will emerge. Some of these trends include:

- At least one short-period binary is usually required in a dynamical interaction to produce another binary having a similarly short-period (provided no stars are ejected with escape velocities $\gtrsim 100$ km/s). This is because the orbital energy of a short-period binary is sufficiently negative that it tends to considerably outweigh the other energy terms in Equation 1 for most of the encounters that typically occur in the cores of globular and especially open clusters. This has been confirmed by Hurley et al. (2005).
- Previous studies have found that in order for triples to remain stable for many dynamical times, the ratio of their inner to outer orbital periods must be relatively large (roughly a factor of ten or more) (e.g. Mardling 2001). Based on our results, this has two important corollaries for stellar mergers in dense cluster environments hosting a significant population of triples:

- (i) The longest-lived triples will contain very hard inner binaries with a large $|\epsilon|$. This is important since stellar radii are in general more likely to overlap and hence mergers to occur during resonant interactions involving very hard binaries (e.g. Fregeau et al. 2004; Hurley et al. 2005). We therefore expect stellar mergers to be common during encounters involving stable triple systems.
- (ii) The longest-lived triples will contain wide outer orbits, creating a large cross section for collision. This suggests that the time-scale required for a stable triple system to encounter another object is typically short relative to the cluster age in dense environments. A significant fraction of encounters involving very hard binaries, and hence resulting in stellar mergers, will therefore involve triples in old open clusters such as M67 and NGC 188.

van den Berg et al. (2001) and Sandquist et al. (2003) suggest that back-to-back binary-binary encounters, or even a single 3+3 encounter, could have formed S1082. We have improved upon these previous studies by estimating time-scales required for possible dynamical formation scenarios to

occur. Since we have argued in Section 3 that the formation of S1082 must have involved at least 6 stars, it follows that only a 3+3 interaction could have reproduced the observed configuration via a single encounter. However, the derived 3+3 encounter time-scale is sufficiently long that we expect very few, if any, 3+3 encounters occurred within the lifetime of a typical merger product. Moreover, we have argued that the times for multiple encounters to occur are longer than the cluster age. Although we cannot rule out a dynamical origin for S1082, our results suggest that it is unlikely (provided the derived encounter time-scales were not significantly higher in the recent past, which we will return to below). From this, it follows that a dynamical link between the close binary and third star is unlikely to exist.

On the other hand, we have so far ignored the cluster evolution, and assumed that the currently observed cluster parameters have not changed in the last few Gyrs. N-body models suggest that the central density in M67 could have been significantly higher in the recent past. Specifically, Figure 5 of Hurley et al. (2005) indicates that the presently observed central density in M67 could have been higher within the past Gyr by a factor of $\gtrsim 2$. If this was indeed the case, our previous estimates for each of the different encounter frequencies should increase by a factor of ~ 4 , so that a significant number of dynamical encounters involving single, binary and triple stars should have occurred in M67 within the last τ_{BS} years. It follows that a dynamical origin for S1082 is not unlikely if the central density in M67 was recently larger than its presently observed value by a factor of $\gtrsim 2$. This also increases the probability that a scenario involving multiple encounters created S1082, although we have shown that such a scenario is still likely to have involved one or more triples.

Based on the preceding arguments, S1082 offers an excellent example of how observations of individual multiple star systems containing BSs can be used to directly constrain the dynamical history of their host cluster. If a definitive dynamical link between components A and B is established, this would suggest that the central density in M67 was higher in the last 1-2 Gyrs. This is also required in order for the cluster dynamics to have played a role in the formation of a significant fraction of the observed BS population in M67. Based on the current density, the encounter time-scales are sufficiently long that too few encounters should have occurred in the last τ_{BS} years for mergers during dynamical interactions to be a significant contributor to BS formation.

We have obtained quantitative constraints for two generic channels for mergers during encounters involving triples – one in which a direct stellar collision occurs within a dynamical interaction of the hard inner binary of a triple and another single or (hard) binary star (Mechanism I) and one in which the hard inner binary of a triple is driven to coalesce by imparting energy and/or angular momentum to other stars involved in the interaction (Mechanism II). Our results suggest that these two general merger mechanisms could contribute to a bi-modal period distribution for BS binaries similar to that observed in NGC 188. These dual mechanisms predict a gap in period, with those BS binaries formed via Mechanism I having periods of a few to ~ 100 days and those formed via Mechanism II having periods closer to ~ 1000 days. Some 2+2, 2+3 and even 1+3

encounters could involve orbits with periods in this range, and Equation 9 confirms that the final period of a BS binary formed via Mechanism II will typically be determined by that of the second hardest binary orbit. Therefore, we might still expect some BS binaries to have periods that fall in the gap ($100 \text{ days} \lesssim P \lesssim 1000 \text{ days}$). Our results do indeed predict one such BS binary, as shown in Figure 3.

A number of assumptions went into obtaining Figure 3, many of which were chosen specifically to reproduce the observed BS binary period distribution. Regardless, our assumptions were chosen to reflect encounter scenarios that are the most likely to result in mergers. These should involve triples with very hard inner binaries since these are the most likely to merge during encounters. The triples should also have outer companions on very wide orbits since these have the largest cross sections for collision. From this, we have assumed a ratio of 30 between the inner and outer semi-major axes of all triples. This ensures that all triples are dynamically stable. This also leads us to assume a minimum period of 400 days for the outer orbits of triples so that the corresponding minimum period of their inner orbits is not too small. These assumptions serve to show that encounters involving triples could produce both long-period and short-period BS binaries as well as a period gap.

Our results predict that the short-period peak in Figure 3 is at a slightly longer period than the observations suggest. If we decrease the assumed ratio between the inner and outer orbital separations of triples, the short-period peak will move to even longer periods. However, if one or more stars were ejected with a high escape velocity or the dissipative effects of tides are considered (which are expected to be the most significant for encounters involving hard binaries) this would move the short-period peak to even shorter periods. In order to obtain the desired agreement with the observations at the short-period end of the BS period distribution, energy must have somehow been dissipated or removed from the hard inner binaries of the triples during (or even after) the encounter, or the inner binaries must have initially been even harder than we have assumed in obtaining Figure 3.

Our results could suggest that the hard BS binaries in NGC 188 (binaries 5078 and 7782) may have outer triple companions, perhaps with sufficiently long periods that they would have thus far evaded detection. This is consistent with the requirement for energy conservation since the orbital energy of the outer orbit of the triple is negligible compared to that of its inner binary. If binaries 5078 and 7782 do have outer triple companions, it is also possible that Kozai oscillations combined with tidal friction contributed to decreasing their orbital periods (Eggleton 2006). Finally, the BS binaries in NGC 188 are observed to have a wide range of eccentricities, which we have argued is not inconsistent with a dynamical origin involving triples.

We have assumed that Mechanism II is more likely to occur than Mechanism I during any given 1+3 encounter. This is a reasonable assumption since numerical scattering experiments of 1+2 and 2+2 encounters have shown that the coalescence of a hard binary is much more likely to occur during an encounter than a direct collision between a hard binary and an interacting single or binary star (e.g. Fregeau et al. 2004). The ratio we have assumed for the frequencies with which Mechanisms I and II occur was specifi-

cally chosen in order to reproduce the observed numbers of short- and long-period BS binaries. The important point to take away is that the observed BS binary period-eccentricity distribution offers a potential constraint on the fraction of encounters that result in different merger scenarios.

Based on our results, Mechanism II must occur ~ 4 times more often than Mechanism I in order to reproduce the observed BS period distribution from 1+3 encounters (or, equivalently, 2+3 encounters involving a very wide binary and 2+2 encounters between a short-period binary and a long-period binary). This can be tested by performing numerical scattering experiments of encounters involving triples. Therefore, our results highlight the need for simulations of 1+3, 2+3 and 3+3 encounters to be performed in order to better understand their expected contributions to BS populations in open and globular clusters. Once a preferred encounter scenario has been identified for an observed binary or triple containing one or more BSs, numerical scattering experiments can be used to further constrain the conditions under which that scenario will occur (or to show that it cannot occur). We have demonstrated that a combination of observational and analytic constraints can be used to isolate the parameter space relevant to the dynamical formation of an observed multiple star system (or population of star systems) containing one or more merger products. This will drastically narrow the relevant parameter space for numerical scattering experiments.

We have improved upon the results of Perets & Fabrycky (2009) and Mathieu & Geller (2009) since we have shown that dynamical encounters involving triples could not only be contributing to the long-period BS binaries in NGC 188, but they could also be an important formation mechanism for short-period BS binaries and triples containing BSs. We have not ruled out mass transfer or Kozai-induced mergers in triples (primordial or otherwise) (Mathieu & Geller 2009; Perets & Fabrycky 2009), or even various combinations of different mechanisms, as contributing formation channels to the BS binary population in NGC 188. For instance, a 1+3 exchange interaction could stimulate a merger indirectly if the resulting angle of inclination between the inner and outer orbits of the triple exceeds $\sim 39^\circ$, ultimately allowing the triple to evolve via the Kozai mechanism so that the eccentricity of the inner binary increases while its period remains roughly constant (Eggleton 2006).

There is evidence to suggest that mass transfer via Roche lobe over flow could play a role in the formation of at least some BSs. It is difficult to account for the near zero eccentricities of some of the long-period BS binaries without at least one episode of mass transfer having occurred. This is because none of the normal MS-MS binaries with similar periods have such small eccentricities (Mathieu & Geller 2009). On the other hand, it may not be unreasonable to expect that some collision products left in binaries undergo mass transfer since they are expected to expand adiabatically post-collision, and will sooner or later evolve to ascend the giant branch. As a result of conservation of energy and angular momentum, the mass transfer process will usually act to increase the orbital periods of these binaries provided it is conservative (Iben 1991). Interestingly, the cut-off period for Roche lobe overflow is ~ 1000 days for low-mass stars (Eggleton 2006), which is in rough agreement with the

long-period peak in the observed period-eccentricity distribution of the BS binary population in NGC 188. Therefore, mass transfer could also be contributing to the period gap observed for the BS binaries.

According to the results of Geller et al. (2009), the number of giant-MS binaries with $P \lesssim 1000$ days is comparable to the number of BS binaries (A. Geller, private communication). It is unlikely that every giant-MS binary will form a BS from mass transfer, however, suggesting that at most a few of the long-period BS binaries in NGC 188 were formed via this mechanism. Finally, if the outer companion of a triple system evolves to over-fill its Roche lobe it could transfer mass to both of the components of the close inner binary. This mechanism could therefore also produce two BSs in a close binary, although it predicts the presence of an orbiting triple companion. For these reasons, a better understanding of triple evolution, as well as binary evolution in binaries containing merger products, is needed.

The dissipational effects of tides tend to convert stars' bulk translational kinetic energies into internal or thermal energy within the stars, leading to an increase in the total gravitational binding energy of the stellar configuration (e.g. McMillan, Hut & Makino 1990). By increasing the terms U_{ii} in Equation 1, the initial orbital energies of any binaries going into an encounter can increase accordingly in order to conserve energy. A higher orbital energy corresponds to a larger semi-major axis and hence cross section for collision. This suggests that the derived encounter time-scales can be taken as upper limits in the limit that tidal dissipation is negligible. We expect tides to be particularly effective during encounters for which the total energy is very negative as a result of one or more very hard binaries being involved.

We have argued in Section 2.2 that the average stellar mass is expected to be comparable to (but slightly less than) the mass of the MSTO in old OCs and low-mass GCs. We have also argued that most encounters will involve stars having masses slightly larger than the average stellar mass. We might therefore expect to find that a high proportion of merger products have masses that exceed that of the MSTO in very dynamically-evolved clusters that have lost a large fraction of their low-mass stars. Consequently, a larger number of merger products could appear sufficiently bright to end up in the BS region of the cluster CMD in these clusters than in their less dynamically-evolved counterparts. This is consistent with the results of Knigge, Leigh & Sills (2009) and Leigh, Sills & Knigge (2009) who found that the number of BSs in the cores of GCs scales sub-linearly with the core mass. In particular, since the cluster relaxation time increases with increasing cluster mass, it is the lowest mass GCs that should have lost the largest fraction of their low-mass stars. Therefore, if a larger fraction of merger products do indeed end up more massive than the MSTO in these clusters, this could be a contributing factor to the observed sub-linear dependence on core mass. It is also interesting to note that, since BSs are among the most massive cluster members and many are thought to have a binary companion, BSs should be preferentially retained in clusters as they evolve dynamically compared to low-mass MS stars. This could also contribute to the observed sub-linear dependence on core mass.

The exchange or conversion of energies that occurs during an encounter takes place over a finite period of time, so

it is important to specify whether or not the system has fully relaxed post-encounter when discussing the remaining stellar configuration. For one thing, Sills et al. (2001) showed that, although collision products may be in hydrodynamic equilibrium, they are not in thermal equilibrium upon formation and so contract on a thermal time-scale. Simulations also suggest that most merger products should be rapid rotators (Sills et al. 2002, 2005). However, at least in the case of blue stragglers, this is rarely supported by the observations. Some mechanism for angular momentum loss must therefore be operating either during or after the merger takes place in order to spin down the remnant. The time-scale considered must also be sufficiently short that subsequent dynamical interactions are unlikely to have occurred since these could affect the total energy and momentum of the system.

With this last point in mind, N-body simulations considering BS formation have shown that after they are formed, BSs are often exchanged into other multiple star systems (Hurley et al. 2005). This suggests that for multiple star systems containing more than one BS, the BSs could have first been formed separately or in parallel, and then exchanged into their presently observed configuration. For the case of S1082, this would require at least 3 separate dynamical interactions. Given that the derived times between encounters are relatively long and the fact that the most likely formation scenario is usually that for which the number of encounters is minimized, the current state of M67 suggests that the probability of S1082 having formed from a scenario involving 3 encounters is low. Conversely, the derived encounter time-scales in NGC 188 are sufficiently short that many of the BS binaries could have experienced a subsequent dynamical interaction after their formation. BSs tend to be more massive than normal MS stars, contributing to an increase in their gravitationally-focussed cross section for collision. This suggests that the encounter time-scale for multiple star systems containing BSs is slightly shorter than for otherwise identical systems composed only of normal MS stars. This contributes to a slight increase in the probability that a BS will experience an exchange encounter after it is formed. Interestingly, it could also contribute to an increase in the probability that a close binary containing two BSs will form during an encounter between two different multiple star systems each containing their own BSs (Mathieu & Geller (2009); R. Mathieu, private communication). This is because it is the heaviest stars that will experience the strongest gravitational focussing and are therefore the most likely to experience a close encounter, end up in a closely bound configuration, or even merge.

Most exchange interactions will involve wide binaries for which the cross section for collision is large. Since wide binaries are typically relatively soft and the hardest binary involved in the interaction will usually determine the orbital energy of the left-over BS binary, most exchange interactions will leave the periods of BS binaries relatively unaffected. This need not be the case, of course, provided one or more stars are ejected from the system with a very high escape velocity. With these last points in mind, we have assumed throughout our analysis that all binaries and triples are dynamically hard. This is a reasonable assumption since the hard-soft boundary corresponds to a period of $\sim 10^6$ days in both M67 and NGC 188, for which the cross section for collision is sufficiently large that we do not expect such bi-

naries to survive for very long. Nonetheless, considerations such as these must be properly taken into account when isolating a preferred formation scenario and predicting the final distribution of energies.

We have presented an analytic technique to constrain the dynamical origins of multiple star systems containing one or more BSs. Our results suggest that, in old open clusters, most dynamical interactions resulting in mergers involve triple stars. If most triples are formed dynamically, this could suggest that many stellar mergers are the culmination of a hierarchical build-up of dynamical interactions. Consequently, this mechanism for BS formation should be properly included in future N-body simulations of cluster evolution. A better understanding of the interplay between the cluster dynamics and the internal evolution of triple systems is needed in order to better understand the expected period distribution of BS binaries formed from triples. Simulations will therefore need to track both the formation and destruction of triples as well as their internal evolution via Kozai cycles, stellar and binary evolution, etc. On the observational front, our results highlight the need for a more detailed knowledge of binary and especially triple populations in clusters.

APPENDIX A: COLLISIONAL CROSS SECTIONS AND TIME-SCALES

The gravitationally-focused cross sections for 1+1, 1+2, 2+2, 1+3, 2+3 and 3+3 collisions can be found using Equation 6 from Leonard (1989). Neglecting the first term and assuming that binary and triple stars are on average twice and three times as massive as single stars, respectively, this gives for the various collisional cross sections:

$$\sigma_{1+1} \sim \frac{8\pi GmR}{v_{rel}^2}, \quad (A1)$$

$$\sigma_{1+2} \sim \frac{3\pi Gma_b}{v_{rel}^2}, \quad (A2)$$

$$\sigma_{2+2} \sim \frac{8\pi Gma_b}{v_{rel}^2}, \quad (A3)$$

$$\sigma_{1+3} \sim \frac{4\pi Gma_t}{v_{rel}^2}, \quad (A4)$$

$$\sigma_{2+3} \sim \frac{5\pi Gm(a_b + a_t)}{v_{rel}^2}, \quad (A5)$$

$$\sigma_{3+3} \sim \frac{12\pi Gma_t}{v_{rel}^2}. \quad (A6)$$

Values for the pericenters assumed for the various types of encounters are shown in Table A1, where R is the average stellar radius, a_b is the average binary semi-major axis and a_t is the average semi-major axis of the outer orbits of triples.

In general, the time between each of the different encounter types can be found using Equation 10 and the gravitationally-focused cross sections for collision given

Table A1. Pericenters Assumed for Each Encounter Type

Encounter Type	Pericenter
1+1	$2R$
1+2	$a_b/2$
1+3	$a_t/2$
2+2	a_b
2+3	$(a_b + a_t)/2$
3+3	a_t

above. Following the derivation of Leonard (1989), we can write the encounter rate in the general form:

$$\Gamma_{x+y} = N_x n_y \sigma_{x+y} v_{x+y}, \quad (\text{A7})$$

where N_x and n_y are the number and number density, respectively, of single, binary or triple stars and v_{x+y} is the relative velocity at infinity between objects x and y . For instance, the time between binary-binary encounters in the core of a cluster is given by:

$$\tau_{2+2} = 1.3 \times 10^7 f_b^{-2} \left(\frac{1pc}{r_c} \right)^3 \left(\frac{10^3 pc^{-3}}{n_0} \right)^2 \left(\frac{v_{rms}}{5km/s} \right) \left(\frac{0.5M_\odot}{\langle m \rangle} \right) \left(\frac{1AU}{a_b} \right) \text{years}. \quad (\text{A8})$$

Similarly, the times between 1+1, 1+2, 1+3, 2+3 and 3+3 encounters are given by:

$$\tau_{1+1} = 1.1 \times 10^{10} (1 - f_b - f_t)^{-2} \left(\frac{1pc}{r_c} \right)^3 \left(\frac{10^3 pc^{-3}}{n_0} \right)^2 \left(\frac{v_{rms}}{5km/s} \right) \left(\frac{0.5M_\odot}{\langle m \rangle} \right) \left(\frac{0.5R_\odot}{\langle R \rangle} \right) \text{years}, \quad (\text{A9})$$

$$\tau_{1+2} = 3.4 \times 10^7 (1 - f_b - f_t)^{-1} f_b^{-1} \left(\frac{1pc}{r_c} \right)^3 \left(\frac{10^3 pc^{-3}}{n_0} \right)^2 \left(\frac{v_{rms}}{5km/s} \right) \left(\frac{0.5M_\odot}{\langle m \rangle} \right) \left(\frac{1AU}{a_b} \right) \text{years}, \quad (\text{A10})$$

$$\tau_{1+3} = 2.6 \times 10^7 (1 - f_b - f_t)^{-1} f_t^{-1} \left(\frac{1pc}{r_c} \right)^3 \left(\frac{10^3 pc^{-3}}{n_0} \right)^2 \left(\frac{v_{rms}}{5km/s} \right) \left(\frac{0.5M_\odot}{\langle m \rangle} \right) \left(\frac{1AU}{a_t} \right) \text{years}, \quad (\text{A11})$$

$$\tau_{2+3} = 2.0 \times 10^7 f_b^{-1} f_t^{-1} \left(\frac{1pc}{r_c} \right)^3 \left(\frac{10^3 pc^{-3}}{n_0} \right)^2 \left(\frac{v_{rms}}{5km/s} \right) \left(\frac{0.5M_\odot}{\langle m \rangle} \right) \left(\frac{1AU}{a_b + a_t} \right) \text{years}, \quad (\text{A12})$$

and

$$\tau_{3+3} = 8.3 \times 10^6 f_t^{-2} \left(\frac{1pc}{r_c} \right)^3 \left(\frac{10^3 pc^{-3}}{n_0} \right)^2 \left(\frac{v_{rms}}{5km/s} \right) \left(\frac{0.5M_\odot}{\langle m \rangle} \right) \left(\frac{1AU}{a_t} \right) \text{years}. \quad (\text{A13})$$

ACKNOWLEDGMENTS

We would like to thank Bob Mathieu for many helpful comments and suggestions. We would also like to thank Aaron Geller, Evert Glebbeek, Hagai Perets, David Latham, Daniel Fabrycky and Maureen van den Berg for useful discussions.
